Abstract: Pregnant women are normally screened for Gestational Diabetes Mellitus (GDM) at week 24 of pregnancy. However some women develop the disease later on in their pregnancies. No study has analyzed women developing GDM later in pregnancy. This study will analyze data on a cohort study and compare women diagnosed with GDM in second and third trimester of pregnancy with women without GDM. At the end of analysis, result showed that GDM women diagnosed during their first two trimesters of pregnancy were older (p = 0.0008) and had higher body mass index (BMI) (p = 0.0007) than non-GDM women. However, the only risk factor in women diagnosed in their third trimester of pregnancy was having first degree relatives with type 2 DM and this was independent of age and BMI (OR of 2.7, 95% CI 1.2 - 6.0).Women who develop GDM in their second trimester of pregnancy have known risk factors for diabetes mellitus such as age and higher BMI, however, the only recognized risk factor between non GDM women and women developing GDM late in pregnancy is family history of type 2 DM. In conclusion, where two populations of GDM exists, future studies should focus on analyzing short and long term complications of these women to support the need to diagnose and treat them all.
Keywords: Diabetes Mellitus, gestational, incidence, risk factors.

INTRODUCTION

Gestational diabetes mellitus (GDM) is the most common medical complication of pregnancy. It is associated with maternal and neonatal adverse outcomes. Maintaining adequate blood glucose levels in GDM reduces morbidity for both mother and baby. There is a lack of uniform strategies for screening and diagnosing GDM globally.

The diagnosis of gestational diabetes mellitus (GDM) has been proved to be critical when treating conditions associated to adverse consequences to mother and child. In this regard GDM has been associated with a greater risk of hypertension and Caesarean section and

abortion (Jovanovic et al; 2005). Newborns from GDM mothers have a higher incidence of being large for gestational age (macrosomia)(Schmidt et al;2001,Yang et al;2002), being born preterm(Yang et al;2002), of hypoglicaemia and jaundice(Jensen et al;2000,El Mallah et al;1997) of admission to a neonatal unit(Jensen et al;2000) and perinatal death(Schmidt et al;2001,Akhter et al;1996). GDM has also been associated with long term complications in the mother and in the child. Mothers with previous GDM have higher incidence of type 2 diabetes mellitus (Lee et al; 2007) while their children have higher risk of developing adult obesity and other chronic non-transmissible diseases (Lee et al; 2007). However, not all the studies on GDM support these associations and the discrepancies could be explained by the different methods to diagnose GDM. In this regard, some studies use 75 g-1h OGTT while others use 100 g-2h OGTT, some centers use 200 mg/dl cut-off to diagnose GDM(HAPO;2002) while others agree with the WHO recommendations of a 140 mg/dl cut-off (Mc Intyre et al; 2005). Moreover, some centers test all women while others test only women with recognized risk factors, and some centers test only in second trimester of pregnancy while others retest during the third trimester. These differences in the approach to diagnosing GDM explain not only part of the different prevalence in GDM but also variability in short-and long-term risk associated with GDM. Lowering the cut-off glycaemia or testing more frequently or later in pregnancy would result in both, higher prevalence of GDM but lower risk associated with the diagnosis. To our knowledge, there are no studies comparing GDM women diagnosed in second and third trimester of pregnancy with women who do not develop GDM. This comparison would help knowing if these women share the same risk factors and would enlighten us regarding the benefit of testing all women in late pregnancy. The primary objective of this study was to compare women diagnosed with GDM in second with those diagnosed in third trimester of pregnancy in terms of recognized risk factors for GDM. Secondary objectives were to compare risk factors and delivery outcome between GDM in second and third trimester of pregnancy with non-GDM women.

MATERIALS AND METHODS

Women who belonged to a cohort of pregnant women who attended antenatal care at two hospitals, namely Federal medical Centre Abakaliki and Ebonyi State University Teaching Hospital Abakaliki, from January 2010 to December 2011 were retrospectively enrolled for the study. There involved all pregnant women who attended to antenatal care before week 20 of a single fetus who signed the informed consent. Women were dated between weeks 24 to 28 and between week 34 to 36 of pregnancy for anthropometric measurements and blood

tests. Follow up was completed in 50 women who developed GDM in the first two trimesters of pregnancy and 27 women diagnosed with GDM in the third trimester of pregnancy, along with 327 non-GDM women (70% of the initial cohort). Gestational Diabetes was diagnosed or ruled out according to the classification of the Nigerian Ministerial Norms based on the American Diabetes Association (ADA;1998) plus a second OGTT made to all women during the third trimester of pregnancy to completely rule out the development of diabetes. Data on pregnancy and delivery were extracted from the medical records units. To study recognized risk factors for GDM, we analyzed age, pre-pregnancy weight according to mother's report at recruitment, educational level, marital status, number of previous pregnancies, antecedents in previous pregnancies including abortion, stillbirth, macrosomia, intra uterine growth retardation(IUGR) and congenital malformations. We also analyzed weight, height, fasting glycaemia and insulinaemia, insulin resistance calculated through Homeostasis Modelling Assessment (HOMA), which were records obtained as a result of measurement at recruitment in all the mothers. Weight and height records were obtained based on measurement by the nutritionist with the patients in underwear in an electronic SECA balance with height rod. Glycaemia was measured through glucose oxidase method while insulinaemia was measured through radioimmunoassay technique. HOMA values of 2.5 or over were considered as insulin resistance. To analyze complications associated to GDM, we measured gestational age at delivery, type of delivery, weight and height of the newborn, Apgar score of the newborn and presence of metabolic and trauma complications in the newborn and/or the mother.

DATA ANALYSIS

In the statistical analysis, variables presented as percentages are categorical while those in means and standard deviation (mean ± SD) are continuous. To show the precision of the data, standard error (SE) or 95% confidence interval are presented. Association of recognized risk factors for GDM and characteristics on delivery with GDM were analyzed with Chi Squared, ANOVA and Student T Test as appropriate. We analyzed general data on the whole cohort, followed by the analysis of differences on risk factors and delivery data between non-GDM and GDM groups and separately for non-GDM with each group of GDM women diagnosed in second and third trimester of pregnancy. It was not necessary to transform variables since all of them were normally distributed. Independence of associated variables was tested with logistic regression using stepwise analysis. Statistical analyzes were performed using STATA

9.0 Software. Ethical approval from the research and ethics committee of the two hospitals was obtained.

RESULTS

The cohort consisted in women 16 to 44 years old with a mean of 30.8 ± 5.0 years. Characteristics of the two groups of GDM and non-GDM women are shown in Table 1.The comparison between non-GDM women and GDM women diagnosed in second trimester of pregnancy showed significant differences in education, age, BMI, basal glycaemia and HOMA. GDM women diagnosed in second trimester of pregnancy were less educated (p = 0.036), older (p = 0.0008), had more previous pregnancies (p = 0.004) and had a higher body mass index (BMI) in the pre-pregnancy stage (p = 0.028) and in their first antenatal control (p = 0.0007) than non-GDM women. The number of previous pregnancies was no longer different after adjusting by maternal age (p = 0.15). BMI at pre-pregnancy state and at recruitment were no longer different between GDM at second trimester of pregnancy and non-GDM women after adjusting by age in logistic regression (p = 0.08). In the stepwise logistic regression only age and glycaemia at recruitment were independent predictors of developing GDM in second trimester of pregnancy. The only significant difference between women diagnosed with GDM in their third trimester of pregnancy and non-GDM women was that the formers had a higher percentage of family history of type 2 DM (44.4% vs 22.6%, p = 0.04) and this was independent from age and BMI with an OR of 2.7 (95% CI 1.2 -6.0). Regarding outcomes at delivery, no significant differences were found among the groups in birth weight or height. Newborns from GDM mothers had more complications than babies from non-GDM mothers, but this difference was not statistically significant. Delivery outcomes are shown in Table 2. Women diagnosed with GDM in second trimester of pregnancy gained less weight than non-GDM women (p = 0.0026) and had smaller gestational age than non-GDM women (p = 0.0001). The association between weight gain and GDM development in the second trimester of pregnancy was independent of maternal age, BMI, glycaemia, insulinaemia and HOMA at recruitment (p = 0.026). No difference was found between GDM women diagnosed during third trimester of pregnancy and non-GDM women regarding delivery outcomes. Although these women presented more complications than GDM women diagnosed earlier and with non-GDM women, this difference was not significant.

DISCUSSION

In this analysis of a cohort of women followed by the diagnosis of GDM, we found that those GDM women diagnosed during the third trimester of pregnancy have different risk factors than women diagnosed earlier in pregnancy. In this study, women diagnosed in second trimester are older than non-GDM women, present a higher BMI previous to pregnancy and in their first antenatal visit and have higher fasting glycaemia, higher insulinaemia and higher insulin resistance measured through HOMA. Age, weight and glycaemia are known risk factors for GDM (Debelea et al; 2005) and they could explain GDM development early in pregnancy. However in this cohort, 35% of GDM women developed this disease in their third trimester of pregnancy and they did not differ in recognized risk factors from non-GDM women. The lack of recognized risk factors could mean that these women have unknown risk factors that are probably not as strong as the known ones. This could also explain why these women manifest GDM in later stages of pregnancy. Other possibility is that these women are developing a physiologically different GDM. These women were not as insulin resistant early in pregnancy as the ones that develop GDM in second trimester of pregnancy. Therefore, they could be developing diabetes with predominance in beta cell failure over insulin resistance, resembling Type 1 DM. However, it is remarkable that these women are more likely to have a family history of Type 2 DM. The relationship between family history of Type 2 DM and GDM has been described in a large cohort of Sardinian women in whom GDM could not be predicted by recognized risk factors (Murgia et al; 2008). This relationship has also been shown in a cross sectional study in 1414 GDM women and 1011 controls in which the highest associations were with prior GDM and family history of Type 2 DM (Ogonowshi et al; 2007). In contrast, a study on 90 GDM women with family history of Type 2 DM and 83 women without family history of Type 2 DM showed that recognized risk factors predict better GDM in women with family history of Type 2 DM (Retnakaran et al;2007). A recent study that compares women with GDM diagnosed in the second trimester, GDM diagnosed in the third trimester and non-GDM women did not found differences among the three groups, except that GDM women diagnosed later in pregnancy had higher BMI (Virally et al; 2007). However, this study analyzed only women at high risk for GDM with a prevalence of GDM of 72% and is therefore not comparable to our study. The smaller weight gain in women who developed GDM earlier in pregnancy could be explained by the fact that they were at high risk for GDM and diet to diminish that risk. On the other hand, characteristics on delivery were not different between GDM women diagnosed late in pregnancy and non-GDM women,

while GDM women diagnosed in second trimester of pregnancy delivered earlier their babies. This could be explained by different criteria used by the gynaecologist at the moment of planning the deliveries, since they were aware of the GDM condition of women diagnosed earlier. Other studies demonstrate that complications are not higher in GDM when women are treated intensively for their disease (Virally et al; 2007). One of the factors that justify the diagnosis of GDM is the risk to the child and in this cohort we could not demonstrate this risk, probably because of the limited number of GDM women.

CONCLUSION

GDM women diagnosed in second trimester of pregnancy are older and have higher fasting glycaemia and insulinaemia than women diagnosed with GDM in their third trimester of pregnancy. Women diagnosed later in pregnancy are not different from non-GDM women, but have more family history of type 2 DM. Larger studies should analyze these apparently two different populations of GDM women to estimate the costs and benefits of diagnosing GDM in late pregnancy.
